Convolutional Neural Networks Trading Strategy | CNN

aiquants Research | © Dayton Nyamai

Application of CNNs in Market Direction Prediction

Summary

This project aims to leverage machine learning techniques, specifically Convolutional Neural Network models to develop a trading strategy that can generate consistent profits in the financial markets. By utilizing historical data and advanced algorithms, we aim to identify patterns and trends that can be exploited for profitable trading opportunities.

A histogram providing visual representation of the EUR log returns distribution

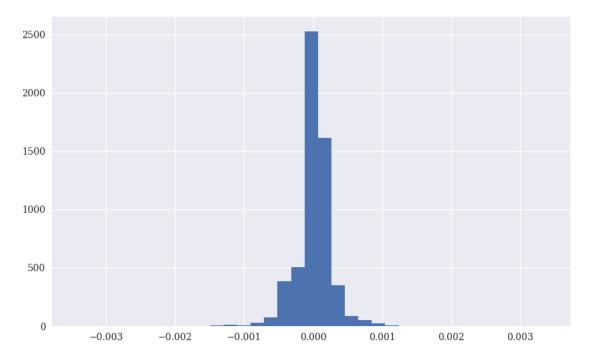

Fig. 1.1 A histogram showing the distribution of EUR log returns

Second, create the features data by lagging the log returns and visualize it in combination with the returns data. We can use various visualization techniques such as scatter plots or line plots to compare the lagged log returns with the returns data.

Create lagged columns

```
[]: lags = 500

cols =[]
for lag in range(1, lags+1):
    col = f'lag_{lag}'
    data[col] = data['returns'].shift(lag)
    cols.append(col)
data.dropna(inplace=True)
```

```
# data.round(6).tail()
```

Scatter plot based on features and labels data

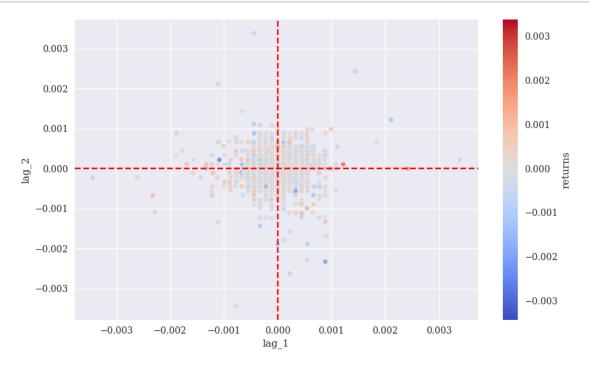

Fig. 1.2 A scatter plot based on features and labels data

With the dataset fully prepared, various deep learning techniques can be employed to forecast market movements based on the provided features. Additionally, these predictions can be utilized to rigorously backtest a trading strategy.

Deep Learning Models: Convolutional Neural Networks

Summary

In this task, we will create Convolutional Neural Networks model for predicting future market movements. We will also utilize the TPU (Tensor Processing Unit) VM cloud infrastructure from Google, for efficient training and inference.

Import the necessary libraries, tensorFlow and its submodules

Split the data into training and test sets

```
[199]: # Split the data into training and test sets
split = int(len(data) * 0.7)
training_data = data.iloc[:split].copy()
test_data = data.iloc[split:].copy()
```

Standardize the training and test data.

```
[200]: mu, std = training_data.mean(), training_data.std()
    training_data_ = (training_data - mu) / std
    test_data_ = (test_data - mu) / std
```

Reshape the training and test data for LSTM input

```
[201]: X_train = np.array(training_data_[cols])
X_train = np.reshape(X_train, (X_train.shape[0], X_train.shape[1], 1))
y_train = np.array(training_data['direction'])

X_test = np.array(test_data_[cols])
X_test = np.reshape(X_test, (X_test.shape[0], X_test.shape[1], 1))
y_test = np.array(test_data['direction'])
```

Build the CNN model

```
model = Sequential()
model.add(Conv1D(filters=64, kernel_size=3, activation='relu',
input_shape=(lags, 1)))
model.add(Conv1D(filters=32, kernel_size=3, activation='relu'))
model.add(MaxPooling1D(pool_size=2))
model.add(Flatten())
model.add(Dense(128, activation='relu'))
model.add(Dense(1, activation='sigmoid'))
```

Compile the model

Train the model

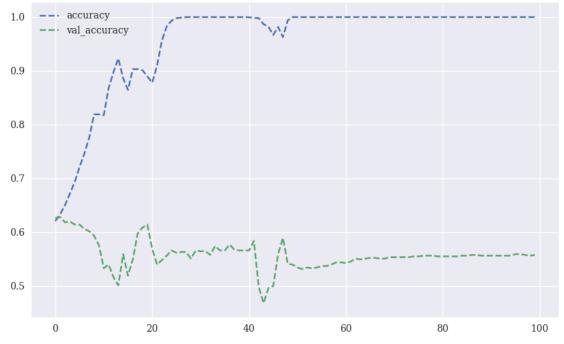

Fig. 1.3 Accuracy of the ML-model on training and validation data per training step

Evaluate the performance of the model on training data

```
[205]: train_loss, train_accuracy = model.evaluate(X_train, y_train)
```

Training Data

Make predictions on the training data

The number of the resulting short and long positions, respectively.

```
[208]: training_data['prediction'].value_counts()
```

[208]: -1 3502 1 128

Name: prediction, dtype: int64

Trading Rules

In the benchmark case, i.e training_data['returns'], we adopt a long position on the asset throughout the entire period. This means that we hold one unit of the asset for the entire duration. On the other hand, in the case of the DNNs strategy, i.e training_data['strategy'], we take either a long or short position on the asset, i.e one unit of the asset.

Calculates the strategy returns given the positions

```
[209]: training_data['strategy'] = training_data['prediction'] *_\(\) \(\tau\) training_data['returns'] training_data[['returns', 'strategy']].sum().apply(np.exp)
```

[209]: returns 1.021256 strategy 1.045892 dtype: float64

Plots and compares the strategy performance to the benchmark performance (in-sample)

Fig. 1.4 Gross performance of EUR/USD compared to the ML-based strategy (in-sample, no transaction costs)

Testing Data

Evaluate the performance of the model on testing data

```
[211]: model.evaluate(X_test, y_test)
```

[211]: [3.105820894241333, 0.5529865026473999]

Make predictions on the test data

49/49 [========] - Os 4ms/step

The number of the resulting short and long positions, respectively.

[213]: test_data['prediction'].value_counts()

```
[213]: -1 1547
1 10
```

Name: prediction, dtype: int64

Calculate the strategy returns given the positions, with the proportional transaction costs included

[214]: returns 0.990303 strategy 1.007555 strategy_tc 1.004099

dtype: float64

Plots and compares the strategy performance to the benchmark performance (out-of-sample)

```
[215]: test_data[['returns', 'strategy', 'strategy_tc']].cumsum().apply(np.exp).

□ plot(figsize=(10, 6));

plt.figtext(0.5, -0.06, 'Fig. 1.5 Performance of EUR/USD exchange rate and □

□ ML-based algorithmic trading strategy', style='italic',ha='center')

plt.figtext(0.5, -0.1, '(out-of-sample, with transaction costs)',□

□ style='italic',ha='center')

plt.show()
```

Fig. 1.5 Performance of EUR/USD exchange rate and ML-based algorithmic trading strategy (out-of-sample, with transaction costs)

Optimal Leverage

Equipped with the trading strategy's log returns data, the mean and variance values can be calculated in order to derive the optimal leverage according to the Kelly criterion.

Annualized mean returns

```
[216]: mean = test_data[['returns', 'strategy_tc']].mean() * len(data) *12
mean
```

```
[216]: returns
                      -0.389546
       strategy_tc
                       0.163542
       dtype: float64
       Annualized variances
[217]: | var = test_data[['returns', 'strategy_tc']].var() * len(data) * 12
       var
[217]: returns
                        0.005774
       strategy_tc
                        0.005779
       dtype: float64
       Annualized volatilities
[218]: vol = var ** 0.5
       vol
[218]: returns
                       0.075989
       strategy_tc
                       0.076017
       dtype: float64
       Optimal leverage according to the Kelly criterion ("full Kelly")
[219]: mean / var
[219]: returns
                      -67.461558
       strategy_tc
                        28.301292
       dtype: float64
       Optimal leverage according to the Kelly criterion ("half Kelly")
[220]:
        mean / var * 0.5
[220]: returns
                      -33.730779
       strategy_tc
                        14.150646
       dtype: float64
```

Using the "half Kelly" criterion, the optimal leverage for the trading strategy is about 30. The graph below shows in comparison the performance of the trading strategy with transaction costs for different leverage values

Scales the strategy returns for different leverage values

```
[221]: to_plot = ['returns', 'strategy_tc']
for lev in [10, 15, 30, 40, 50]:
    label = 'lstrategy_tc_%d' % lev
    test_data[label] = test_data['strategy_tc'] * lev
    to_plot.append(label)
```

```
test_data[to_plot].cumsum().apply(np.exp).plot(figsize=(10, 6));
plt.figtext(0.5, -0.06, 'Fig. 1.6 Performance of ML-based trading strategy for_different leverage values', style='italic',ha='center')
plt.show()
```

 ${\it Fig.~1.6~Performance~of~ML-based~trading~strategy~for~different~leverage~values}$

Risk Analysis

Since leverage increases the risk associated with a trading strategy, a more in-depth risk analysis seems in order. This risk analysis involves calculating the maximum drawdown, which represents the largest loss experienced after a recent high, and the longest drawdown period, which is the duration it takes for the strategy to recover to a recent high. The analysis assumes an initial equity position of 3,333 EUR, resulting in a position size of 100,000 EUR with a leverage ratio of 30. It also assumes that there are no adjustments made to the equity over time, regardless of the strategy's performance.

Initial equity

```
[222]: equity = 3333
```

The relevant log returns time series

```
[223]: risk = pd.DataFrame(test_data['lstrategy_tc_30'])
```

Scaled by the initial equity

```
[226]: risk['drawdown'] = risk['cummax'] - risk['equity']
```

The maximum drawdown value

```
[227]: risk['drawdown'].max()
```

[227]: 1247.6300978018548

The point in time when it happens

```
[228]: t_max = risk['drawdown'].idxmax()
t_max
```

[228]: Timestamp('2023-07-27 11:15:00')

Technically a new high is characterized by a drawdown value of 0. The drawdown period is the time between two such highs. The figure below visualizes both the maximum drawdown and the drawdown periods:

```
[229]: array([datetime.timedelta(seconds=300), datetime.timedelta(seconds=300), datetime.timedelta(seconds=300), datetime.timedelta(seconds=300), datetime.timedelta(seconds=300), datetime.timedelta(seconds=300), datetime.timedelta(seconds=11400), datetime.timedelta(seconds=300), datetime.timedelta(seconds=31800)], datetime.timedelta(seconds=31800)], dtype=object)
```

```
[230]: t_per = periods.max()
t_per
```

[230]: datetime.timedelta(days=2, seconds=61800)

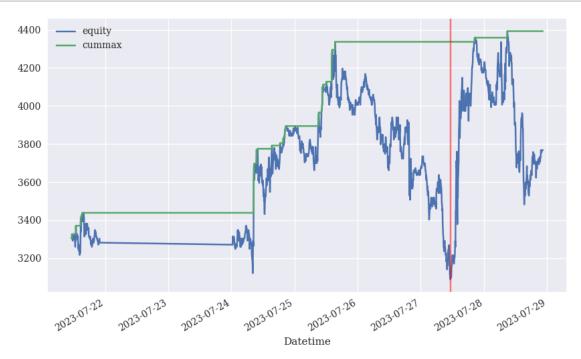

Fig. 1.7 Maximum drawdown (vertical line) and drawdown periods (horizontal lines)

Value-at-Risk (VaR)

VaR, quoted as a currency amount represents the maximum loss to be expected given both a certain time horizon and a confidence level. The code that follows derives VaR values based on the log returns of the equity position for the leveraged trading strategy over time for different confidence levels. The time interval is fixed to the bar length of 5 min:

Defines the percentile values to be used

```
VaR = scs.scoreatpercentile(equity * risk['returns'], percs)

def print_var():
    print('%16s %16s' % ('Confidence Level', 'Value-at-Risk'))
    print(33 * '-')
    for pair in zip(percs, VaR):
        print('%16.2f %16.3f' % (100 - pair[0], -pair[1]))

# Translate the percentile values into confidence levels and the VaR values
print_var()
```

Confidence	Level	Value-at-Risk
	99.99	244.173
	99.90	161.452
	99.00	77.454
	97.50	55.693
	95.00	44.192
	90.00	32.550

VaR values for a time horizon

Time horizon: 1 hour

Resample the original DataFrame object, in effect the VaR values are increased for all confidence levels

Confidence Level	Value-at-Risk
99.99	374.211
99.90	356.497
99.00	203.457
97.50	138.033
95.00	111.350
90.00	77.797
